Review and summary:

Oxygen and nitrogen nucleophiles react reversibly with aldehydes and ketones. Equilibrium constant depends on a number of steric and electronic features. Acid (always) and base (sometimes) can accelerate the processes. Protons equilibrate among all O and N atoms in a mixture, activating each site.

Carbon nucleophiles, in the form of organometallic reagents, can be generated by several methods and are associated with an electropositive metal [Li, Mg, Zn, Al, etc]. Varying degrees of "extra" electron density on the carbon, depending on how electropositive is the metal. They add to carbonyl groups fast and irreversibly, generating an alcohol.

Hydride nucleophiles are available as metal hydrides (LiAlH₄, and NaBH₄ are the prototype cases). Add H⁻ to a carbonyl group, generating an alcohol.

Alcohols can be oxidized to give aldehydes and ketone. Two stragegies:

(a) put leaving group at the oxygen and carry out an E2.

$$\begin{array}{c|c}
R & & & \\
C - OH & & & \\
H & & & \\
\end{array}$$

$$\begin{array}{c|c}
R & & \\
C - O & \\
H & Cl
\end{array}$$

$$\begin{array}{c|c}
H_2O & R \\
R & \\
C = O$$

(b) OR remove hydride (H⁻) from the carbon by reaction with a strong electrophile such as Ph₃C⁺,

Nature's oxidizing agent: NAD

$$= \begin{array}{c} \begin{array}{c} \begin{array}{c} \\ \\ \\ \\ \end{array} \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \end{array} \begin{array}{c} \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\ \end{array} \begin{array}{c} \\ \\ \\ \\$$

nicotinamide adenosine dinucleotide

Acetaldehyde is reactive and toxic--"intense flushing, nausea, dizziness, throbbing headaches.."

Genetic deficiency: alcohol intolerance

Anatbuse: Inhibits the enzyme aldehyde dehydrogenase

Alcohol dehydrogenase also works on MeOH formaldehyde (very toxic) Antidote for MeOH poisoning?

Bio-oxidation mechanism: consider the pyridinium ion:

$$\begin{bmatrix} H & O & H & H & O \\ H & H & H & O \\ NH_2 & & & NH_2 \\ & & & & & & \\ R & & & & & \\ \end{bmatrix} \longrightarrow \begin{bmatrix} H & H & O \\ NH_2 & & & \\ & & & & \\ R & & & & \\ \end{bmatrix} + \begin{bmatrix} H & O & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ \end{bmatrix} + \begin{bmatrix} H & O & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ \end{bmatrix}$$

SUBTLE STEREOCHEMICAL POINT:

$$\begin{array}{ccc} H_A & \text{Any difference between} \\ R & OH & H_A \text{ and } H_B ? & \text{Only in an} \\ H_B & \text{(e.g., enzyme)} \end{array}$$

The protons H_A and H_B are NOT **chemically** equivalent. **Connectively equivalent** (connected to the same other atoms)

Connectively non-equivalent groups are likely to have different chemical reactivity under any conditions.

Chemically non-equivalent groups are different only in the presence of an asymmetric environment

- a. stereogenic center in the same molecule
- b. asymmetric catalyst (e.g., enzyme)

Test: replace (mentally) one H with another group. Is the product asymmetric?

Non-superimposable mirror images?

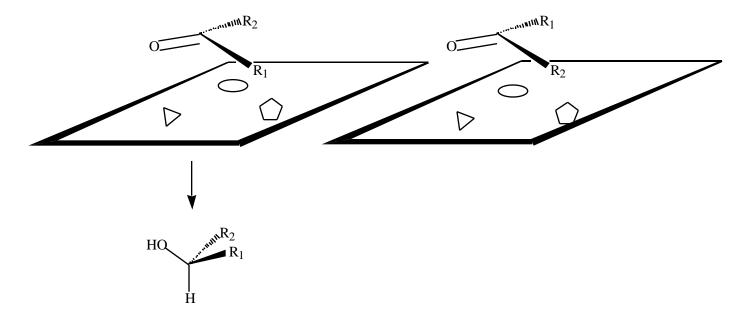

If not, then the H's in question are **homotopic**--chemically equivalent.

If generate new non-superimposable pairs,

- a. if enantiomers (mirror images), then the original H's were enantiotopic
- b. if diastereoisomers, then the original H's were diastereotopic.

As usual, biological reactions can go both directions: NADH is an effective ketone reducing agent:

How does it achieve selective addition?

STABILIZED CARBANIONS:

recall:

$$CH_4$$
 + base CH_3 + H-base

Now: Replace H with other groups that can stabilize a (-) charge.

Typical base: n-Butyl-Li (very strong base and good nucleophile; adds to ketones)

O-Li
$$H_2O$$
 H_2O $H_$

Analogy with the allyl anion.

Favors the ketone, but low barries, rapid equilibration Accelerated by acid and base. How?
