Lecture Notes 16

Reminder: turn in exam regrading request by Monday noon, in my mailbox.

From last time:

$$R-NH_2$$
 + O $RH_2N-C-OH$ H $C-OH$ carbinolamine

 H_2O

$$R_1$$
 R_2
 R_3
 R_2
 R_3
 R_2
 R_3
 R_3
 R_3

NOW: Carbon Nucleophiles. How to make a carbon electron-rich?

a. Proton abstraction?
$$CH_4$$
 + base \longrightarrow CH_3 + H_3C — Li + LiX $X = Cl, Br, I$

c. halogen-metal exchange
$$H_3C-X + RLi$$
 \longrightarrow $H_3C-Li + RX$

$$X = Cl, Br, I$$

Equilibrium depends on relative stability of components, primarily depends on R-Li vs Me-Li:carbanion stability

d. metal-metal exchange
$$H_3C-M + M'-X \longrightarrow H_3C-M' + R-M$$

$$X = Cl, Br, I$$

Equilibrium depends on relative stability of components, more electropositive M prefers X

Eg,
$$H_3C-Li + ZnX_2$$
 \longrightarrow $H_3C-Zn-X + Li-X$

Very common case: the Grignard reagent

halide insertion (not F)
$$H_3C-X + Mg$$
 \longrightarrow $H_3C-Mg-X$ $X = Cl, Br, I$

What about Na and K?

Wurtz reaction...

Relative reactivity of R-M correlates roughly with electropositive value for M:

more electropositive M more (-) on CH₃ more reactive nucleophile

ADDITION TO KETONES AND ALDEHYDES:

$$H_3C-Mg-X + O \xrightarrow{fast} O -Mg-X \xrightarrow{H_3C} O-Mg-X$$
Alcohol synthesis

Essentially irreversible (CH₃- is a lousy leaving group)

In general:

General alcohol synthesis from ketones and aldehydes:

$$R - X + Mg \xrightarrow{\text{ether}} R - Mg - X$$

$$X = Cl, Br, I$$

$$R - Mg - X$$

$$R - Mg - X$$

$$R_2 \xrightarrow{R_2} O - Mg - X$$

$$R_2 \xrightarrow{H/H_2O} R_2 \xrightarrow{H/H_2O} R_3 \xrightarrow{H/H_2O} R_4 \xrightarrow{R_1} O - H$$

$$R - Mg - X$$

$$R_2 \xrightarrow{R_1} O - Mg - X$$

$$R_2 \xrightarrow{H/H_2O} A$$

$$R_3 \xrightarrow{H/H_2O} A$$

$$R_4 \xrightarrow{H/H_2O} A$$

$$R_4 \xrightarrow{H/H_2O} A$$

$$R_5 \xrightarrow{H/H_2O} A$$

$$R_7 \xrightarrow{H/$$

Hydrogen as a nucleophile:

$$\bigoplus_{Li} \bigoplus_{AlH_4} + \bigvee_{R_2} \bigcap_{ether} \bigoplus_{ether} \left[\begin{matrix} H_1 & H_2 \\ H_1 & H_2 \\ H_2 & H_1 \end{matrix} \right] - \bigvee_{R_2} \bigcap_{H_1} \bigcap_{R_2} \bigcap_{R_2}$$

Many variations on the theme: differing in reactivity by electronic and steric parameters.

LiAlH₄ reacts with all types of carbonyl groups: ketones, aldehydes, etc. and imines, nitriles

NaBH₄: Less reactive--can react selectively with aldehydes. Not at all with other carbonyl derivatives, including esters, amides, etc.

Note stereochemical issues:

A. Enantiomers

Addition of organometallic reagents to ketones and aldehydes

Addition of hydride reagents to ketones:

B. Diastereomers:

Should not be 1:1 (unless accidentally equal energy TS)

Reverse of Hydride Reduction: Oxidation of Alcohols to Ketones Special case of elimination: Oxidation of alcohols

Elimination to form C=O

Is this an oxidation? Reduction/oxidation in organic chemistry a little fuzzy

How arrange the lowest energy **pathway** for oxidation of an alcohol to a ketone??

Z = good electron acceptor

How arrange Z group efficiently? CrO₃ is one example

Clorox oxidation:

$$\begin{array}{c|c}
R \xrightarrow{C} -OH & \xrightarrow{NaOCl} & R \xrightarrow{C} -O \\
H & Cl & R
\end{array}$$

$$\begin{array}{c|c}
H_2O & R \\
R & C=O$$

Consider Alternate Activation: Hydride Transfer

E⁺ could be a carbocation is stabilized by three phenyl groups Ph₃C⁺ X⁻
